A Comparison of Salivary Mercury Levels in Children with Attention Deficit/Hyperactivity Disorder When Compared to Age-matched Controls: A Case-control Observational Study

Mohammed J Barry¹, Fatmah Almotawah², Sharat C Pani³, Navin A Ingle⁴

ABSTRACT

Aim: The aim of this study was to compare the level of mercury in the saliva of children with attention deficit/hyperactivity disorder (ADHD) as compared to age- and gender-matched controls in specific age groups.

Materials and methods: A case-control observational study design was used. In school children with ADHD and outpatient dental clinics of a university dental hospital, the participants were schoolchildren diagnosed with ADHD studying in the first grade (6–7 years), sixth grade (12–13 years), and ninth grade (15–16 years) and were gender-matched to children without ADHD attending regular classes in school. Ninety children with ADHD comprised the test group while 90 children without ADHD comprised the control group.

Results: In this study, we found that children with ADHD had higher levels of salivary mercury than their age- and gender-matched counterparts; however, this difference was significant only in the 6–7 years of age group. The regression model showed a mild positive association between salivary mercury and ADHD; however, the association was not statistically significant.

Conclusion: While there is some indication that salivary mercury may be higher in children with ADHD, there is insufficient evidence to establish a definite association between the two.

Clinical significance: The study highlights the need to evaluate existing evidence on the role of mercury, especially salivary mercury, in ADHD.

Keywords: Attention deficit hyperactivity disorder, Dental amalgam, Mercury, Saliva.

INTRODUCTION

Attention deficit/hyperactivity disorder (ADHD) is one of the most common mental disorders affecting children. Attention deficit/hyperactivity disorder also affects many adults. Symptoms of ADHD include inattention (not being able to keep focus), hyperactivity (excess movement that is not fitting to the setting), and impulsivity (hasty acts that occur in the moment without thought).¹

The prevalence of ADHD in children in the west has been reported as being between 2% and 5.5%.¹⁻² In Saudi Arabia, there have been studies that have placed the prevalence of ADHD at being between 2.7% and 4.2% on average,³ with reports of incidence as high as 7% in male students.³⁻⁵ It is generally accepted that the prevalence of ADHD reduces with age with the typical adult rates being between 1.2% and 2.7%.²

The role of heavy metals in the development of the brain and neurological disorders is well-documented.⁶⁻⁸ Of the several heavy metals, mercury has received the greatest attention as it is associated with both seafood as well as several preservatives used in food ingredients.⁹⁻¹¹ However, the role that mercury has played in the incidence of diseases such as Autism or ADHD has been controversial in the past. There have been several studies to show that the trace amounts of mercury found in vaccines or in dental products may be associated with ADHD; however, the models proposed fail to prove a causal relationship.¹²⁻¹⁴

Saliva is a useful noninvasive screening tool for several heavy metals, including mercury. Salivary analysis of mercury provides a relatively easy measure to compare mercury levels in children with ADHD and those without ADHD.¹⁵⁻¹⁷ While few studies have successfully shown increased mercury levels in the blood, urine, and saliva of individuals with ADHD,¹³,¹⁴,¹⁹ there has been no systematic attempt made to evaluate the age, demographic, or oral health factors that could influence the levels of mercury in the saliva of children with ADHD when compared to age- and gender-matched controls.

While few studies have successfully shown increased mercury levels in the blood, urine, and saliva of individuals with ADHD,¹³,¹⁴,¹⁹ there has been no systematic attempt made to evaluate the age, demographic, or oral health factors that could influence the levels of mercury in the saliva of children with ADHD when compared to age- and gender-matched controls.

The study of oral health of children is difficult to calibrate due to the changing dentition and the corresponding oral health changes associated with them. The World Health Organization (WHO) has therefore suggested the use of specific ages or age groups to make sample collection easier. They recommend the age of 5 years to evaluate children in the primary dentition, 12 years to record the

Effect of mixed dentition, and 15 years to record the initial effects of young permanent dentition.20

The aim of this study was to compare the level of mercury in the saliva of children with ADHD as compared to age- and gender-matched controls in specific age groups. The study also sought to examine the role of maternal salivary mercury levels, if any, on the presence or absence of ADHD in the children.

Materials and Methods

Study Design

A case-control, observational study design was used.

Ethical Approval

The proposal was registered with the research center of the Riyadh Elm University and Ethical Approval was obtained from the Institutional Review Board (IRB) of the Riyadh Elm University (RC/IRB/2019/64). Approval was obtained from the Al Jawdah Private school in Riyadh city for children with ADHD for examining the medical records of the children. Informed consent was obtained from the parents of all children before accessing records and examination. Verbal assent of the children was obtained before examination and collection of saliva.

Sample Power Calculation

The sample power was calculated using a sample power calculator (G-Power 3.0, Universität Kiel, Germany). It was estimated that in order to obtain an effect size of 0.5 and a power of 0.95, a minimum of 30 participants per group were required. Using the presence or absence of ADHD and the three index age groups as indicators, it was determined that the sample would need 180 participants to achieve the required power.

Sample Setting and Selection

The sample was drawn from schoolchildren studying in the first grade (6–7 years), sixth grade (12–13 years), and ninth grade (15–16 years). Children diagnosed with ADHD as per the Vanderbilt diagnostic score and attending a special school for children with ADHD comprised the test group. The sample comprised of 30 children with ADHD and 30 controls in each age group. Ninety children with ADHD comprised the test group while 90 children without ADHD comprised the control group. These children were age- and gender-matched with a control group. Each index age group comprised of a case group of 30 children with ADHD who were age- and gender-matched with a control group.

When the salivary mercury levels were compared between males and females, it was observed that although females had a slightly higher mean salivary mercury level (5.87 μg/L, SD ±1.2 μg/L) than males (5.75 μg/L, SD ±1.4 μg/L), these differences were not statistically significant (t = −5.32, p = 0.561). When the salivary mercury levels were compared among the different age groups, it was observed that the 6–7-year-old age group had a significantly lower salivary mercury level than the other two age groups (Table 1).

Children with ADHD had higher salivary mercury levels than children without ADHD. However, these differences were only significant in the 6–7-year-old age group (Table 2).

The binary logistic regression model showed that although there was a positive association between salivary mercury levels of the children and ADHD, the strength of association fell short of being statistically significant (p = 0.67) (Table 3).

Discussion

There is an increased concern over the role of mercury in the etiology of neurodevelopmental disorders of childhood especially ADHD.1-3 Despite the known detrimental effect of mercury on the development of the central nervous system, definitive proof of association has remained elusive.4,5 The aim of this study was to examine the levels of salivary mercury in children with ADHD and compare them to age- and gender-matched controls.
Factors Influencing Salivary Mercury Level

While blood mercury testing remains the definitive source for the testing of mercury levels, there have been studies that have focused on the use of noninvasive samples such as saliva and hair to determine mercury levels. The development of CV-AAS for the determination of mercury levels has been shown to be an effective measure of mercury in both food and substrates such as saliva. Given the age of the population being studied and the accuracy of measures such as CV-AAS, we decided to use saliva as the sample for mercury in children.

The fact that we found mildly elevated levels of mercury in the saliva of children with ADHD is not conclusive of any causative relationship. However, when combined with the mildly positive association seen in the children, it seems to suggest merit to the theory proposed by some authors that mercury may play an associative rather than causative role in the development of ADHD. The index age groups used in this study suggested that while there was some difference in the salivary mercury levels of children with ADHD and those without in the primary dentition (6–7 years) age group, this difference was not significant with the children in the mixed (12–13 years) and permanent (15–16 years) age groups. The results of our matched study design seem to support this hypothesis and are in keeping with the studies of Karouna-Renier et al. and Van Wijngaarden et al. that suggest a low level of evidence between prenatal mercury level and ADHD.

One of the limitations of using saliva as a sample to estimate mercury is the possible confounding factors that dentition, diet, and development play in the expression of salivary metals. However, to overcome this bias, the WHO suggests the use of index age groups. The index age groups used in this study suggested that while there was some difference in the salivary mercury levels of children with ADHD and those without in the primary dentition (6–7 years) age group, this difference was not significant with the children in the mixed (12–13 years) and permanent (15–16 years) age groups. This finding could explain the observations of Lygre et al., who found that the association between the presence of a maternal dental amalgam restoration and ADHD was inversely associated with the age of the child. While the metabolism of mercury in children is beyond the scope of this study, the results of this study seem to suggest that future research could look into the possible reasons

bVariable(s) entered on step 1: maternal amalgam, age group, salivary mercury (child), salivary mercury (adult)
Factors Influencing Salivary Mercury Level

for this inverse association between age and mercury levels as it is related to ADHD.

The results of this study should also be viewed keeping in mind the limitations of the observational study design. While all attempts were made to match the age and gender of children being studied, it was not possible to quantify the severity of the ADHD. Given the large variations in the scores used for the diagnosis of ADHD, it was decided to limit the focus of the current study to the presence or absence of ADHD. A further limitation of the current study was that while the presence of maternal dental amalgam restorations was determined clinically, the presence of the restoration during the pregnancy was based on the reported history. Despite these limitations, the fact that there was some positive association between the salivary mercury levels of the child and presence of ADHD seems to suggest that we cannot fully rule out the role mercury in the etiopathogenesis of ADHD.

**Conclusion**

Within the limitations of the study, we can state that the following:

- Children with ADHD seem to have a significantly higher level of salivary mercury than age- and gender-matched controls; however, this difference is the highest in the primary dentition and reduces in the permanent and mixed dentitions.

- The data in this study do not show sufficient association between ADHD and salivary mercury to determine mercury as a cause of ADHD.

- There seems to be evidence to suggest that the association between salivary mercury and ADHD is not a causative one, but an association that merits further research.
